The Shift to Multicore

- Since 2005, improvements in system performance mainly due to increasing cores per chip
- Why? Technology scaling
  Limited instruction-level parallelism

End of Dennard Scaling

What factors may limit multicore performance?

- Limited application parallelism
- Memory accesses and inter-core communication
- Programming complexity
Amdahl’s Law

• Speedup = \( \frac{\text{time}_{\text{without enhancement}}}{\text{time}_{\text{with enhancement}}} \)
• Suppose an enhancement speeds up a fraction \( f \) of a task by a factor of \( S \)

\[
\text{time}_{\text{new}} = \text{time}_{\text{old}} \cdot \left( (1-f) + \frac{f}{S} \right)
\]

\[
S_{\text{overall}} = \frac{1}{(1-f) + \frac{f}{S}}
\]

Corollary: Make the common case fast
Amdahl’s Law and Parallelism

• Say you write a program that can do 90% of the work in parallel, but the other 10% is sequential.
• What is the maximum speedup you can get by running on a multicore machine?

\[ S_{\text{overall}} = \frac{1}{(1-f) + \frac{f}{S}} \]

\[ f = 0.9, \quad S=\infty \quad \Rightarrow \quad S_{\text{overall}} = 10 \]

What \( f \) do you need to use a 1000-core machine well?
Communication Models

- **Shared memory:**
  - Single address space
  - Implicit communication by reading/writing memory
    - Data
    - Control (semaphores, locks, barriers, ...)
  - Low-level programming model: threads

- **Message passing:**
  - Separate address spaces
  - Explicit communication by send/rcv messages
    - Data
    - Control (blocking msgs, barriers, ...)
  - Low-level programming model: processes + inter-process communication (e.g., MPI)

- **Pros/cons of each model?**
Coherence & Consistency

• Shared memory systems:
  – Have multiple private caches for performance reasons
  – Need to provide the illusion of a single shared memory

• Intuition: A read should return the most recently written value
  – What is “most recent”?

• Formally:
  – Coherence: What values can a read return?
    • Concerns reads/writes to a single memory location
  – Consistency: When do writes become visible to reads?
    • Concerns reads/writes to multiple memory locations
Cache Coherence Avoids Stale Data

A cache coherence protocol controls cache contents to avoid stale cache lines.
Implementing Cache Coherence

• Coherence protocols must enforce two rules:
  – Write propagation: Writes eventually become visible to all processors
  – Write serialization: Writes to the same location are serialized (all processors see them in the same order)

• How to ensure write propagation?
  – Write-invalidate protocols: Invalidate all other cached copies before performing the write
  – Write-update protocols: Update all other cached copies after performing the write

• How to track sharing state of cached data and serialize requests to the same address?
  – Snooping-based protocols: All caches observe each other’s actions through a shared bus (bus is the serialization point)
  – Directory-based protocols: A coherence directory tracks contents of private caches and serializes requests (directory is the serialization point)
Snooping-Based Coherence
(Goodman, 1983)

Caches watch (snoop on) bus to keep all processors’ view of memory coherent.
Snooping-Based Coherence

- Bus provides serialization point
  - Broadcast, totally ordered

- Controller
  - One cache controller for each core “snoops” all bus transactions
  - Controller
    - Responds to requests from core and the bus
    - Changes state of the selected cache block
    - Generates bus transactions to access data or invalidate

VI Problems?
Every write updates main memory
Every write requires broadcast & snoop

Cache interventions

- MSI allows caches to serve writes without updating memory, so main memory can have stale data
  - Core 0’s cache needs to supply data
  - But main memory may also respond!
- Cache must override response from main memory

MSI Optimizations: Exclusive State

- **Observation:** Doing read-modify-write sequences on private data is common
  - What’s the problem with MSI?

- **Solution:** E state (exclusive, clean)
  - If no other sharers, a read acquires line in E instead of S
  - Writes silently cause E→M (exclusive, dirty)
**MESI: An Enhanced MSI protocol**

*increased performance for private read-write data*

*Each* cache line has a tag

- **M**: Modified Exclusive
- **E**: Exclusive, unmodified
- **S**: Shared
- **I**: Invalid

---

**State Transitions**

- **PrWr** / **BusRd** *if other sharers*
- **PrRd** / **--** *if no other sharers*
- **BusRd** / **BusWB**
MSI Optimizations: Owner State

• Observation: On M→S transitions, must write back line!
  – What happens with frequent read-write sharing?
  – Can we defer the write after S?

• Solution: O state (Owner)
  – O = S + responsibility to write back
  – On M→S transition, one sharer (typically the one who had the line in M) retains the line in O instead of S
  – On eviction, O writes back line (or another sharer does S→O)

• MSI, MESI, MOSI, MOESI...
  – Typically E if private read-write >> shared read-only (common)
  – Typically O only if writebacks are expensive (main mem vs L3)
Split-Transaction and Pipelined Buses

Atomic Transaction Bus
- Supports multiple simultaneous transactions
  - Higher throughput
  - Responses may arrive out of order
- Often implemented as multiple buses (req+resp)

Simple, but low throughput!

Split-Transaction Bus
- Supports multiple simultaneous transactions
  - Higher throughput
  - Responses may arrive out of order
- Often implemented as multiple buses (req+resp)
Non-Atomicity $\rightarrow$ Transient States

- Protocol must handle lack of atomicity
- Two types of states
  - Stable (e.g. MSI)
  - Transient
- Split + race transitions
- More complex

Scaling Cache Coherence

• Can implement ordered interconnects that scale better than buses...

Starfire E10000 (drawn with only eight processors for clarity). A coherence request is *unicast* up to the root, where it is serialized, before being *broadcast* down to all processors.

• ... but broadcast is fundamentally unscalable
  – Bandwidth, energy of transactions with 100s of cache snoops?
Directory-Based Coherence

- Route all coherence transactions through a directory
  - Tracks contents of private caches → No broadcasts
  - Serves as ordering point for conflicting requests → Unordered networks

Coherence and False Sharing

Performance Issue #1

| state | blk addr | data0 | data1 | ... | dataN |

A cache block contains more than one word and cache coherence is done at the block-level and not word-level.

Suppose $P_1$ writes $\text{word}_i$ and $P_2$ writes $\text{word}_k$ and both words have the same block address.

**What can happen?** The block may be invalidated (ping-pong) many times unnecessarily because addresses are in the same block.

**How to address this problem?**
Cache coherence protocols will cause mutex to ping-pong between P1’s and P2’s caches.

Ping-ponging can be reduced by first reading the mutex location (non-atomically) and executing a swap only if it is found to be zero (test&test&set).
In general, an *atomic read-modify-write* instruction requires two memory (bus) operations without intervening memory operations by other processors.

In a multiprocessor setting, bus needs to be locked for the entire duration of the atomic read and write operation:

- expensive for simple buses
- *very expensive* for split-transaction buses

Modern processors use

- *load-reserve*
- *store-conditional*
Load-reserve & Store-conditional

Special register(s) to hold reservation flag and address, and the outcome of store-conditional

Load-reserve \( R, (a) \):
\[
<\text{flag}, \text{adr}> \leftarrow <1, a>;
R \leftarrow \text{M}[a];
\]

Store-conditional \( (a), R \):
\[
\text{if } <\text{flag}, \text{adr}> == <1, a> \\
\quad \text{then cancel other procs’ reservation on } a; \\
\quad \text{M}[a] \leftarrow <R>_; \\
\quad \text{status } \leftarrow \text{succeed}; \\
\text{else status } \leftarrow \text{fail};
\]

If the snooper sees a store transaction to the address in the reserve register, the reserve bit is set to 0

- Several processors may reserve ‘a’ simultaneously
- These instructions are like ordinary loads and stores with respect to the bus traffic
Performance:  
Load-reserve & Store-conditional

The total number of memory (bus) transactions is not necessarily reduced, but splitting an atomic instruction into load-reserve & store-conditional:

- *increases bus utilization* (and reduces processor stall time), especially in split-transaction buses

- *reduces cache ping-pong effect* because processors trying to acquire a mutex do not have to perform stores each time
Thank you!
